for

ELECTRONICALLY CONTROLLED ENGINE GENERATOR SET

5

CROSS REFERENCE TO RELATED APPLICATION

This application claims priority from, and incorporates by reference in its entirety, U.S. Provisional Application No. 60/156,402, filed on September 28, 1999.

10

TECHNICAL FIELD OF THE INVENTION

The present invention is related to the field of electric power production using combustion engines. It is further related to methods of control of electric power systems responding to load changes.

15

BACKGROUND OF THE INVENTION

In an engine/generator system, the fuel supply to the prime mover is directly controlled by an actuator means, generally with a throttle or injection pump. Fuel supply adjustment is a method of adjusting the
20 torque/speed characteristics of the prime mover. As the throttle is closed or the fuel injection setting reduced, the torque produced at a given rotational velocity is similarly reduced, causing the system to slow down, while wide open throttle maximizes the torque and power output at a given speed. In conventional engine/generator systems, the speed of the system is
25 controlled by altering the torque/speed characteristic of the prime mover. This results in engine inefficiency.

An additional cause of engine inefficiency is friction. As the piston moves through the cylinder, work must be done because of friction between the piston and the cylinder. Every time the piston moves through a stroke, some
30 energy is lost, regardless of engine power output for that piston stroke. The greater the energy output per piston stroke, the less energy lost to friction as compared to energy output.

Other sources of engine inefficiency are parasitic loads such as oil pumps and the like, which vary with engine speed, but not power output. The
35 higher the RPM of the engine, the more energy lost to these loads, regardless

Proprietary and Confidential • Property of Borealis Technical Limited
Application for Patent of Jonathan Sidney Edelson, Filed: 28 September 2000
Title: **Electronically Controlled Engine Generator Set**   Page 1 of 75

of actual engine power output. Parasitic loads and cylinder friction mean
that for constant power output, lower RPM will generally be more efficient.

BACKGROUND HYBRID ELECTRIC VEHICLES

A partial solution for inefficiency during low demand is found in systems comprising an energy storage unit (such as a battery) besides the engine-generator system. An example for such system is the Hybrid Electric

5 Vehicle (HEV), in which the solution for the inefficient low load mode is simply to turn the engine and generator off. The power demand is supplied by the battery until a higher demand is required or until the battery reaches a low energy level. The engine and the generator are then turned on to recharge the battery and to supply power, directly or via the battery, to the

10 vehicle.

Attempts to deal with engine inefficiency, such as with the hybrid electric vehicle have not been successful. HEVs have a problem in that involved in their usage is a substantial amount of restarting of the engine and generator, which releases fumes and is a particularly inefficient period

15 in engine operation. Secondly, when the engine is turned off, a great amount of inertial energy is lost. This results in a waste of energy, invested in regaining the inertial energy, when the engine is restarted. Third, no currently available energy storage system is perfect; more energy must be supplied to the energy storage system than is later removed as useable

20 electricity, with the difference being lost as heat. Energy storage systems also have limited life, in terms of number of charge/discharge cycles, and aging due to deep discharge. Even in the hybrid electric vehicle, there is substantial utility to a wide range of generator power output, providing efficiency can be maintained over this range.

25

BACKGROUND ELECTRICAL POWER CONVERSION

Methods for the conversion of electrical power at a given voltage, current, and frequency, to electrical power at a different voltage, current, or frequency are well known in the art. The simplest device, the

30 transformer, is used to trade voltage for current with little loss of power to inefficiency.

Other devices convert input electrical power to an output electrical power via intermediate mechanical form, or from alternating current to alternating current of different characteristics via intermediate direct

35 current. Power electronics are devices that usually contain transistors or

Proprietary and Confidential • Property of Borealis Technical Limited
Application for Patent of Jonathan Sidney Edelson, Filed: 28 September 2000
Title: **Electronically Controlled Engine Generator Set**   Page 3 of 75

similar components, and use switches to vary the electrical characteristics of their output, according to requirements. These include many variations, some of which are the bipolar transistor, the darlington pair of transistors, the field effect transistor, the pulse width modulated DC controller, the

5   Silicon Controlled Rectifier, the DC link converter, the insulated gate bipolar transistor, the silicon controlled rectifier, the MOS controlled thyristor, as well as optically driven devices, vacuum devices, gas filled devices, and even mechanical devices. Power electronic devices can often act as variable pseudo-resistance, that is they can create voltage/current output

10   relationships without dissipating power in the fashion of an actual resistor. The Silicon Controlled Rectifier can control how much AC power is delivered to a load.

BACKGROUND ELECTRIC GENERATORS' CONTROL APPARATUS

15   Electric control systems for generators are well known in the field of the art. Output of a desired frequency, voltage and current can either be achieved by controlling the operational state of the generator, or by converting the native output power of the generator to the desired voltage, frequency, current, or otherwise characterized output power.

20   Output characteristics of a generator are not independent, and are related by load considerations and generator internal characteristics. For example, a DC generator feeding a resistive load, when under circumstances that increase the output voltage of the generator, will also experience an increase in current flow. Often various changes in output are described with

25   other output aspects held constant.

ENGINE-GENERATOR SYSTEMS AND POWER EQUILIBRIUM

Engine-generator systems, in which an engine is directly mechanically linked to a generator, and providing the generator with power in the forms of

30   torque and speed, turn at a fixed speed relation. Torque supplied by the engine is not necessarily equal to the torque absorbed by the generator. If, due to some perturbation, the generator is unable to absorb all the torque that the prime mover provides, a potentially dangerous situation may arise, for the system is not operating in equilibrium. Usually, it is the speed of

35   the engine, and with it, the speed of the generator, which will change when

Proprietary and Confidential • Property of Borealis Technical Limited
Application for Patent of Jonathan Sidney Edelson, Filed: 28 September 2000
Title: **Electronically Controlled Engine Generator Set**   Page 4 of 75

the system is not operating in equilibrium, and in the case mentioned above, the speed of the system will probably increase. Sometimes the fixed mechanical linkage between the engine and generator includes some sort of gearing or mechanical advantage. In this case, then when the system is operating in equilibrium, there will be an equilibrium between the individual linkages between motor and gearing mechanism, and between gearing mechanism and generator.

The term "torque load", in the course of this specification, is used to mean the amount of torque which the generator absorbs from the engine or other prime mover, to which it is connected. It is also described as the torque in the direction counter to rotation that the generator applies to a transmission with the prime mover. A negative torque load would refer to a torque in the direction of rotation (i.e. the generator acting as a motor). The "torque of the generator" refers to the torque applied by the generator to the prime mover, in the direction of, or counter to, rotation. The prime mover in most cases may be an engine, but the term engine is used in the course of this specification to also refer to other prime movers which behave similarly to engines, with the characteristics which will be henceforth described.

An example of how torque equilibrium, or lack thereof, can affect speed, is shown in starting an engine-induction generator system, in which the induction generator is supplying electricity to a fixed frequency, fixed voltage, electrical load. When an engine-generator system is started, the speeds of the engine and generator are in fixed relation to each other, but the torques of the individual parts of the system are not. The engine is producing a torque in the direction of rotation, and for equilibrium, the generator would have to be producing an equal torque in the direction counter to rotation. However, since the speed is so low, the generator does not yet generate electricity. In fact, due to the low speeds, the generator absorbs electricity (from another power source) and produces torque in the same direction as rotation. Therefore, the torque produced by the engine is not absorbed by the generator, resulting in system speed acceleration. However, as high enough speeds are reached, the generator begins to generate electricity, and to absorb the torque produced by the engine. There is (in a matched system) at least one equilibrium point, at which the torque output of the engine matches the torque absorbed by the generator, whereupon the system ceases acceleration, and a steady speed is maintained. When changes in

Proprietary and Confidential • Property of Borealis Technical Limited
Application for Patent of Jonathan Sidney Edelson, Filed: 28 September 2000
Title: **Electronically Controlled Engine Generator Set**   Page 5 of 75

system output are required, these are usually made by throttling the engine, or similar methods. Throttling acts to change the torque/speed characteristics of the engine. When throttling is used, the system will often change speed to a different torque equilibrium point, due to the new

5   engine characteristics.

In all examples of engine-generator systems, each of the engine and the generator will have a characteristic that describes how its torque changes with speed. These characteristics will determine the equilibrium speed of the combined engine/generator system.

10   The generator torque/speed characteristics will depend upon the type of generator it is, its level of excitation, and the load to which it is supplying electricity. Induction generators, when attached to electrical loads having fixed voltage, fixed frequency characteristics, are known to be quite stable, being that within the speed range at which they generate

15   electricity, they have a steep torque requirement relative to their speed requirement. Thus an accidental speed change in a system involving an induction generator will be immediately followed by a large torque change, which normally causes the system to return to equilibrium speed.

Note that in the pathological condition of the engine providing greater

20   torque output than the maximum torque load of the generator, system speed will continue to increase until the internal friction of the engine prevents further speed increase, or until the system fails. This is known as a runaway condition. The maximum torque of an induction generator is limited by the load current. A sudden reduction in load will reduce the maximum

25   torque load of the induction generator, and may cause a runaway condition.

In AC induction machines a method may be applied for the alternation between generator and motor modes. The synchronous speed, the speed of the rotating magnetic field, of the induction machine is determined by the number of poles of the machine and the frequency of the applied AC power. The

30   synchronous speed is given by the formula: **Ns = 120 f / P** where: **Ns** is the Synchronous speed in rotations per minute; **f** is the frequency of the power supply in cycles per second; and **P** is the number of poles for which the machine is wound.

In induction generators the actual speed of the rotor is faster than

35   the synchronous speed of the rotating field. In induction motors the actual speed of the rotor is lower than the synchronous speed of the rotating field.

Proprietary and Confidential • Property of Borealis Technical Limited
Application for Patent of Jonathan Sidney Edelson, Filed: 28 September 2000
Title: **Electronically Controlled Engine Generator Set**   Page 6 of 75

In fact, the motor and the generator are essentially the same machine with the main difference being in their actual speed in relation to their synchronous speed; induction machines that are marketed as motors are often placed into service as generators. Although a generator is supplying real

5   electrical power to a load, it is consuming reactive power for excitation purposes. If an induction machine does not have a source of excitation power, then it will not develop a rotating magnetic field, and will not act as a generator.

By controlling the frequency of the input power to the excitation, a

10   controller may increase or decrease the synchronous speed of the machine. For a given rotor RPM, the control may increase or decrease the synchronous speed to be faster or slower than the rotor RPM thereby determining the function of the induction machine as a generator or a motor.

US patent 6054844 granted to Frank describes a system in which the

15   torque applied by a motor/generator to the engine is calculated and applied to force the engine torque to have an ideal relationship to the calculated engine speed. Frank's methods of controlling the engine involve calculations and lookup tables as to how much torque the motor must force the engine to adopt so that the speed/torque relationship of the engine follows an ideal

20   operating line. Another point Frank describes is how the engine is switched off if its speed is too low as to have non-ideal conditions. Furthermore, Frank's system is described only with reference to vehicles, and does not include other applications of engine-generator sets. Whilst the Frank apparatus controls engine power output via the torque/speed curve reflected

25   from the wheels, with corrections for CVT dynamics terms, a need remains for a system which controls engine power output in a fashion which is independent of wheel loads.

SUMMARY OF THE INVENTION

30   The present invention comprises a generator driven by, and connected to, a prime mover, typically a heat engine. The generator is connected to a load and to an electronic control system.

The present invention controls fuel consumption, power output and heat engine operation, by electronic control of the torque/speed characteristics

35   of the generator. This electronic control of torque/speed characteristics is

Proprietary and Confidential • Property of Borealis Technical Limited
Application for Patent of Jonathan Sidney Edelson, Filed: 28 September 2000
Title: **Electronically Controlled Engine Generator Set**   Page 7 of 75

obtained either by direct control of generator excitation, or by indirect control of the voltage/current or frequency characteristic of the load. Control of the system by electronic control of the generator allows for heat engine operation in a wide open throttle condition, while being able to

5   operate over a large speed range. The quantity of fuel consumed per piston stroke is maximized, and the energy output per piston stroke remains essentially constant. Power output of the engine/generator system is regulated by controlling the number of piston strokes per second. In general, feedback does not directly control engine speed, but instead power

10   output.

In a further embodiment of the present invention, a throttle or fuel metering is used to maintain the charge of fuel and air in the cylinder at a predetermined maximum level. For maximum efficiency, a throttle operated near the wide open condition may be used. Such a throttle may also find use

15   as an emergency shutdown device, in the event of an electrical failure. As used in the method of the present invention, such a throttle does not take part in the primary control of engine operation.

A further embodiment of the present invention is to dynamically control the torque/speed characteristics of the generator in synchronism with the

20   cyclic torque changes of the power output of the heat engine. The generator may act as a motor for part of the heat engine cycle, powering the heat engine during power absorbing strokes of the cycle. This facilitates the use of single cylinder engines, and engines without flywheels.

Objects of the present invention are, therefore, to provide new and

25   improved methods and apparatus for prime mover-generator systems and control over them, having one or more of the following capabilities, features, and/or characteristics:

A technical advantage of the present invention is that it provides new and improved methods and apparatus for prime mover generator systems and

30   control over them. A further technical advantages is to provide a heat engine generator system in which the heat engine can be continuously operated over a wide load range without induction restriction, avoiding the need for engine throttling.

Another technical advantage of the present invention is that higher

35   engine efficiency is obtained by avoiding engine operation in a near closed throttle mode. Further, the heat engine does not have to be turned on and

Proprietary and Confidential • Property of Borealis Technical Limited
Application for Patent of Jonathan Sidney Edelson, Filed: 28 September 2000
Title: **Electronically Controlled Engine Generator Set**   Page 8 of 75

off in response to demand, but rather the engine runs steadily. This avoids the fumes and pollution caused when a heat engine starts and prevents the loss of rotational energy that occurs from repeated stopping and starting.

A further technical advantage of the present invention is that it provides a heat engine generator system in which control is applied to the generator to electronically regulate the output of the system. Thus, control over the output of the system may be faster and more exact. Further, the load on the heat engine may be electrically manipulated to maintain a close to optimal run of the engine.

A still further technical advantage of the present invention is that it provides a method by which a generator may be operated periodically as a motor. This allows the heat engine operation, during power absorbing strokes, to be improved by a periodic transfer of power from the generator, acting as motor, back to the engine. Thus, the present invention provides a simple method by which an electrical machine may alternate between generator and motor operation without direct control intervention, and without need to synchronize controller operation to heat engine operation.

Other technical advantages of the present invention are set forth in or will be apparent from drawings and the description of the invention that follows, or may be learned from the practice of the invention.

BRIEF DESCRIPTION OF THE DRAWINGS

For a more complete explanation of the present invention and the technical advantages thereof, reference is now made to the following description and the accompanying drawings, wherein like reference numerals represent like parts, in which:

Fig. 1 illustrates an embodiment of the present invention;

Fig. 2A shows one embodiment of the present invention in starting mode or during power absorbing strokes of the engine;

Fig. 2B illustrates one embodiment of the present invention in running operation during power strokes;

Fig. 3 is a graph of engine and generator torques in one embodiment of the present invention;

DETAILED DESCRIPTION OF THE INVENTION

Embodiments of the present invention and their technical advantages may be better understood by referring to Figs. 1 though 9, like numerals referring to like and corresponding parts of the various drawings.

Fig. 1 shows a schematic overview of the present invention. Prime mover 11 is connected to an electric generator 12 via shaft 18. Generator 12 is connected to power electronic converter 13 via wiring 20. Converter 13 is further connected to electrical load 14 and energy storage unit 16.

Figs. 2 show a schematic overview of power flows in the present invention when the heat engine is a single cylinder engine. The bold arrow represents the instantaneous direction of the power flow. Fig. 2A represents the system in starting mode or during power absorbing strokes of the engine 11A, when the generator 12 is powered by the energy storage unit 16 and driven to act as a motor. Fig. 2B represents the system in running operation

during the power strokes. The generator 12 is powering the electrical load 14 and charging the electrical storage unit 16.

Fig. 3 is a graph of the engine and generator torques in one embodiment of the present invention. The engine is a single cylinder diesel engine
5   coupled to an appropriately sized induction generator. The horizontal axis of the graph is time, while the vertical axis of the graph is torque in the direction of rotation. The horizontal axis is divided amongst the four strokes of the engine.

Fig. 4 is a torque/speed diagram for an internal combustion engine and
10   a DC generator coupled to a set of resistive loads. Curve M represents the torque/speed characteristic of this example engine, with the horizontal axis representing rotational velocity, and the vertical axis representing torque in the direction of rotation. Curves G, G', G'', G''',...,G''''' represent the torque/speed characteristics of the example DC generator under various
15   load resistance conditions, with the horizontal axis again representing rotational velocity, but with the vertical axis representing torque in the direction counter to rotation.

Fig. 5 is a torque/speed diagram for an internal combustion engine and an AC induction generator coupled to a power electronic control. Curve M
20   represents the torque/speed characteristic of an example engine, with the horizontal axis representing rotational velocity, and the vertical axis representing torque in the direction of rotation. Curves G, G', G'',...,G''''' represent the torque/speed characteristics of the example AC generator operating at various drive frequencies and a constant
25   voltage/frequency ratio. The power electronic drive is designed to maintain proper voltage while both sourcing and sinking power.

Fig. 6 is a torque/speed diagram for an internal combustion engine and a DC generator coupled to a power electronic load accepting current at various threshold voltages. Curve M represents the torque/speed
30   characteristic of an example engine, with the horizontal axis representing rotational velocity, and the vertical axis representing torque in the direction of rotation. Curves G, G', G'', G''',...,G'''''' represent the torque/speed characteristics of the example DC generator under various load conditions, with the vertical axis representing torque in the direction
35   counter to rotation. The load in this case is designed to have little current flow until a programmed threshold voltage, followed by increasing

current flow at an incremental resistance of 2.5 ohms, meaning that for every 10 volts above the threshold voltage, current increases by 4 amps.

Fig. 7 is a torque/speed diagram for an internal combustion engine and a DC generator coupled to a power electronic load accepting current at various threshold voltages, with the additional capability of sourcing current. Curve M represents the torque/speed characteristic of an example engine, with the horizontal axis representing rotational velocity, and the vertical axis representing torque in the direction of rotation. Curves G, G'', G''',...,G'''''' represent the torque/speed characteristics of the example DC generator under various load conditions, with the vertical axis representing torque in the direction counter to rotation. The load in this case is designed to source current to the generator until a programmed threshold voltage, followed by increasing current flow at an incremental resistance of 2.5 ohms, meaning that for every 10 volts above the threshold voltage, current consumption increases by 4 amps. The generator will operate as a motor until it reaches a rotational velocity set by the threshold voltage, at which point it will begin to source power to the load.

Figs. 8 are schematic diagrams of power electronic loads. Fig. 8A is a representation of a boost converter with feedback drawn from the input. Fig. 8B is a representation of a boost converter load combined with buck converter power supply to cause the generator to act as a motor at low voltage levels.

Figs. 9 are schematic diagrams of the use of an automotive alternator in the method of the present invention. Fig. 9A is the arrangement of the alternator in the method of the present invention. Fig. 9B is a torque/speed diagram for an internal combustion engine and an alternator supplying power to a battery. The alternator has adjustable excitation. Curve M represents the torque/speed characteristic of an example engine, with the horizontal axis representing rotational velocity, and the vertical axis representing torque in the direction of rotation. Curves G, G',G'',..., G'''''' represent the torque/speed characteristics of the example alternator under various excitation conditions, with the vertical axis representing torque in the direction counter to rotation. In this case, the load is simply a battery. Current through the alternator rectifier is essentially zero until the alternator voltage matches battery voltage, at which point current and torque begins to rise rapidly. Alternator voltage may be adjusted by adjusting excitation.

In the method of the present invention, the power output of the heat engine/generator system is controlled by electrical manipulation of the torque/speed characteristics of the generator. The present invention comprises a heat engine, an electric generator, and a power electronic

5   control. Electrical energy storage, in addition to suitable control means for the same, may additionally be used. A load consumes the electrical power produced. To facilitate understanding, the common diesel engine rotating an induction generator system will be used to describe a particular embodiment of the present invention. The present invention may be used with all common

10   internal combustion engines, including Otto cycle engines, two stroke engines, and rotary engines, as well as with other prime movers whose potential energy consumption may be controlled by the RPM of the prime mover. The common feature of diesel engines, Otto cycle engines, two stroke engines, and Wankel rotary engines is that air intake and fuel burned are directly

15   controlled by the rotational velocity of the engine. The greater the number of engine cycles per second, the more fuel burned, and the greater the power output. Other devices, for example piston engines operated by steam pressure, share the common feature that rotational velocity determines potential energy consumed and thus, power output.

20   The heat engine is directly coupled to the generator, via a mechanical means, such as a shaft, or gearing or other speed changing apparatus. The generator converts mechanical power into electrical power, and driving an output current through a load. The torque/speed relation of the generator is electronically controlled, either by direct control of generator excitation,

25   or by control of load voltage/current or load frequency characteristics. Through control of the torque/speed characteristics of the generator, control of the system's rotational velocity is effected without the use of a throttle. The heat engine is operated at wide open throttle, with power variation being achieved through changes in rotational velocity.

30   To achieve variation in system power output, the speed of the engine is changed to produce the desired power output at wide open throttle condition. The speed of the generator is the same as, or related to, the speed of the prime mover to which it is connected.

In the method of the present invention, the speed of the system can be
35   indirectly manipulated by altering the relationship between the generator's torque requirements and its speed. The engine/generator equilibrium speed is

changed, and the system moves to this new speed. In general, higher engine speed means more fuel consumption and more power output, thus, control of system power output is achieved through the manipulation of generator torque/speed characteristic.

5   The manipulation of generator torque/speed characteristic can be done, for example, in two ways: a switching or changeable load or by changing the excitation magnitude or frequency of the generator. When using a switching or changeable load, the load can be made to draw more or less current. This will increase or decrease the torque requirements, or "torque load" of the
10   generator.

When changing the excitation magnitude or frequency of the generator, the characteristics of the power supplied to the load is changed. In the case of AC machines, the excitation frequency sets the synchronous speed of the generator. In the case of both AC and DC machines, the excitation
15   current sets the strength of the magnetic field in the generator, and thus, the voltage output at a particular RPM.

An AC induction generator contains stator windings which both provide output as well as excitation. The frequency and voltage of the excitation can be modified to produce a difference in the torque load of the generator.
20   The excitation is provided by quadrature AC, that is alternating current in which the current is not in phase with the voltage. Quadrature AC in the stator windings induces current in the rotor windings, and the current in the rotor windings generates the magnetic field. The induction machine excitation can be controlled through the use of power electronics. They can
25   arbitrarily draw current out of phase with the voltage, and can thereby adjust the quadrature current flowing in an induction machine. The power electronic may comprise an inverter, such as is used to operate induction motors in variable speed applications. The use of the inverter allows for direct control of synchronous speed, and thus, control of the equilibrium
30   point between heat engine torque and generator load. The power electronics can also change the voltage that the system is operating at, which will change the excitation current levels. Power electronics can also control the total current drawn, and in this fashion can also adjust machine torque and power output.

35   Similarly, for the synchronous generator, synchronous speed is frequency controlled. A synchronous generator works in the following manner.

Proprietary and Confidential • Property of Borealis Technical Limited
Application for Patent of Jonathan Sidney Edelson, Filed: 28 September 2000
Title: **Electronically Controlled Engine Generator Set**   Page **14** of 75

In the synchronous machine, the stator poles are magnetized with a rotating magnetic field. The north stator pole is magnetically attracted to the south rotor pole, and the south stator pole is attracted to the north rotor pole. In generator action the north and south poles of the rotor are slightly ahead

5   of their stator opposites and pull them along. Unlike induction machines, the synchronous machine's rotating magnetic field is rotating at the same velocity as the rotor, which is known as the synchronous speed. However, there is ability for control over the torque load of the generator, in the angular difference between the equivalent poles of the rotor and stator.

10   This angular difference is directly related to the torque load of the generator on the prime mover.

       Control of AC synchronous machines may thereby be achieved through the control of the frequency and voltage applied to the terminals of the machine. The applied frequency can differ only slightly from the actual rotational

15   velocity of the rotor, or the machine will fall out of synchronism. Slight changes in drive frequency will cause the rotor to speed up or slow down in order to return to synchronism. The rotor poles would then, after that brief moment of change, although being in synchronism with the stator poles, be slightly more ahead of, or slightly closer to, their stator equivalents. In

20   this state the generator would be applying a different torque load on the prime mover. Making controlled changes in drive frequency and/or drive voltage may be used in the method of the present invention to actively control the torque load, and thereby the speed and total power output of the prime mover.

25   The output of the synchronous generator may also be converted, using suitable apparatus, for example an AC input switching power supply may be used to increase the current drawn by the load, again increasing power output and torque load upon the prime mover.

       In the case of the DC generator, generator torque load is nearly linear

30   in output current level. Thus, one may dynamically adjust the torque load by changing load resistance, for example, through the use of a DC-DC converter. Generator torque load is also nearly linear with field excitation, thus, generator torque load may be controlled by adjustment of the field, if a suitable load is being supplied.

Proprietary and Confidential • Property of Borealis Technical Limited
Application for Patent of Jonathan Sidney Edelson, Filed: 28 September 2000
Title: **Electronically Controlled Engine Generator Set**   Page 15 of 75

An AC synchronous generator with a wound rotor, driving a DC load through suitable rectification means, will operate similarly to a DC generator, as described above, and with similar control capabilities.

As stated above, the speed of the engine/generator system is set by torque equilibrium. If, when the system is in equilibrium at a particular speed with a particular torque equilibrium, the torque/speed characteristic of the generator is changed, then for that particular speed the generator will now have a different torque. The torques of the system will no longer be in equilibrium and the speed of the engine will usually change. When the speed of the engine changes, the speed of the generator changes too. The engine/generator system will speed up or slow down depending upon the net total torque between engine and generator.

In the case of a heat engine coupled to an induction generator supplying a constant voltage load, a slight reduction in the excitation frequency will lower system synchronous speed. As the generator's slip has now increased, its torque load will be greater. This will cause the system to slow down. An increase in synchronous speed will decrease the torque load of the generator, and cause the system to speed up. Note that the power electronic controller may be required to source or sink additional drive power during these speed changes, and that the extent of the speed changes will be limited by the maxima of the torque speed characteristics of the generator. If drive frequency is changed such that the generator is operating well above synchronous speed, then the torque maximum may be passed and torque may be reduced.

In the case of a heat engine coupled to a DC generator, a slight reduction in the excitation current will decrease the voltage output of the generator. Presuming a resistive load, this will reduce the current being driven through the load. The torque requirements of the generator are thereby reduced and the equilibrium speed will be at a higher level. The engine/generator system will speed up. An increase in field excitation will increase the voltage and current, and hence the torque load of the generator and cause the system to slow down. The excitation field is often produced by an electromagnet, allowing the field excitation to be electronically controlled.

The power output changes need not preceded by a closing or opening of a throttle. The imbalance between the torque output of the engine and the

Proprietary and Confidential • Property of Borealis Technical Limited
Application for Patent of Jonathan Sidney Edelson, Filed: 28 September 2000
Title: **Electronically Controlled Engine Generator Set**   Page 16 of 75

torque load of the generator, caused by changes in the electrical characteristics of the generator, changes the speed of the engine. It is the change in engine speed that causes the fuel draw of the engine to change.

5   It should be noted that a change in power requirements does not mean that the power requirement is immediately met by the power output of the generator. In order to reduce the power output of the system, the system speed is reduced. But in order to reduce system speed, the torque load of the generator is increased, in order to cause the RPM change. Power is given by the product of torque and rotational velocity. Thus, the torque has

10   increased, but rotational velocity has not had time to change. To slow the system down in response to a reduction in load, for a moment the power output is increased. Likewise, in response to a required increase in load, for a moment the power output is decreased. Changes are arranged by altering the net torque of the system with the goal of modifying the RPM of the engine,

15   and thereby changing the power output of the system.

The above torque equilibrium may be supplemented and further clarified by consideration of power equilibrium.

In order to maintain and control the speed and power output of the engine while keeping its throttle at the wide open state, the following

20   control procedure may be used:

(One) If the engine is rotating too fast and therefore consuming too much fuel and producing too much power, then more torque is absorbed by the generator and the load, slowing down the engine, or

(Two) if the engine is rotating too slowly, then less torque is absorbed by

25   the generator and the load, causing the engine to speed up.

This control procedure may be understood in terms of the torque balance description presented above. Rotational power is given by the product of torque and rotational velocity. As the engine and generator are locked together in terms of rotational velocity, the only variable is the torque.

30   If the engine torque is greater than the torque being absorbed by the generator, then the engine power will be greater than the power being absorbed by the generator, and the system will speed up. If the engine torque is less than the torque being absorbed by the generator, then the engine power will be less than the power being absorbed by the generator, and

35   the system will slow down.

A throttle not being intrinsic to the present invention, it nevertheless may play a role in such systems. For example, it may be used for emergency overall control, for shutdown, or for very speedy changes, with the method of the present invention used afterwards to achieve a more

5   efficient engine performance, or a throttle may be used to put limits on the amount of fuel the engine may speed up to, for example, when the control over the current being automatic and subject to error or overload.

EXAMPLES

10   As described above, there are numerous generators which may be considered for the present invention, each with several torque control strategies, and all supplying electrical power to a load which itself may be subject to one of several control strategies. Below are specific examples of the present invention, using a few of the many possible combinations of

15   generator, control technique, and load. The following examples are intended to be purely exemplary, and should not be construed to limit the present invention in any fashion.

Example 1 - Changing a Resistive Load on a Generator

20   For example, the present invention may be used with a DC generator supplying a resistive load. Similar results will be obtained from a synchronous AC generator supplying a resistive load with no frequency regulation, or to an AC induction generator with passive supply of excitation, (e.g. a capacitive excitation supply). The immediate example

25   will not work with an AC machine operating on a fixed frequency load.

An engine produces a mechanical power output. This mechanical power is converted by a generator into electrical power. The electrical power is fed to a resistive load where it is dissipated. Due to external control input, decreased power supply is needed (for example, a thermostat has signaled a

30   state of sufficient heat). To reduce the engine power output, the fuel being consumed by the engine is reduced, which is done by slowing the engine down.

To slow the engine down, the torque load of the generator is increased. This may be accomplished by an increase in the power output of the generator.

The generator torque load may be increased by increasing the output current supplied to the load. This may be accomplished by a decrease in the resistance of the load on the generator. More current flows through the lower resistance, and causes the torque load of the generator to be

5   immediately increased. The torque of the system is no longer in equilibrium, the torque of the engine being lower than the torque load of the generator. The speed of the engine decreases, and with it, the engine torque changes according to its torque speed characteristics. When the required engine power output, determined by the product of engine torque and speed, is

10   reached, the load resistance is increased to reduce the generator torque load and restore engine/generator torque equilibrium. Since there is again equilibrium between torque and torque load, the system stops decelerating. At this point the engine is running at a lower speed and with an appropriate torque to maintain that speed and the generator's decreased power requirement

15   is being met. A slightly different method is to decrease the load resistance, and to let the engine/generator system come to equilibrium with the new load resistance. As the engine/generator system slows down, the generator voltage automatically decreases, thus, decreasing the current flow through the resistive load. As the generator torque comes into equilibrium

20   with the engine torque, the system speed will begin to change.

When an increased power supply is desired, the opposite is done. The torque load of the generator is decreased. The load resistance of a resistive load on the generator is increased. This causes the torque load of the generator and the torque of the engine to cease to be in equilibrium, and

25   in this case the speed will increase. When the required engine power output is reached, an increased torque load is applied, equal to the torque output of the engine. The system ceases to accelerate since there is torque equilibrium.

Again, a single step process is possible in which the resistance of the

30   electrical load is simply increased, and the engine/generator allowed to come to equilibrium with the new load.

With reference to Fig. 4, a graph of torque versus speed for both an internal combustion engine and for a DC generator with various resistive loads is shown. To simplify the example, the effects of armature reaction

35   are ignored. Armature reaction is the factor that reduces the voltage output of a generator as its output current increases. Thus, the actual output of

the generator will be somewhat different from the values calculated herein, in that the torque/speed curves for the generator will curve toward horizontal as torque increases, until a maximum current and torque is attained. However the general nature of the output changes will provide a valid example of the method of the present invention. Generator efficiency is also ignored.

The abscissa of the graph of Fig. 4 represents speed in radians per second, while the ordinate of the graph represents torque in meter newtons. Curve M represents the torque of the engine, with positive ordinate values representing power output of the engine, that is torque in the direction of rotation. Curves G, G', G'', G''', etc. represent the torque of the generator with various resistive loads, with positive ordinate values representing power consumption of the generator, that is torque in the direction opposite that of rotation. Curves G, G , G ,G , etc. are labeled with the resistances placed on the generator for each curve. A state of equilibrium is achieved when the total torque on the shaft between engine and generator is zero, that is, when engine torque output is equal to generator torque input. This is represented graphically by the intersection of an engine torque/speed curve and a generator-load torque/speed curve.

The example generator produces 2000 V output at 400 radians per second, with a maximum continuous current rating of 50 A, and a maximum rotational velocity of 500 radians per second. The example internal combustion engine has a slightly curved torque characteristic, ranging from 180 meter newtons at its minimum speed of 50 radians per second, to a peak of 200 meter newtons at 200 radians per second, decaying to 175 meter newtons at its maximum rotational velocity of 400 radians per second.

For example, consider operation of the above system with a 25 ohm load. To describe the 25 ohm load line, two points of the line are calculated. The first point is the torque at zero speed. At a rotational velocity of 0 radians per second, the generator voltage will be 0, and thus, the current flowing through the load will be 0. Generator torque will therefore be 0. At a rotational velocity of 400 radians per second, the generator voltage will be 2000 V, and the current flowing through the load will be 80 amperes, an overload condition. The power output of the generator is 2000 V times 80 A, or 160 kW. To provide 160 kW at 400 radians per second, the generator torque must be 400 meter newtons. The intersection of this load line with

Proprietary and Confidential • Property of Borealis Technical Limited
Application for Patent of Jonathan Sidney Edelson, Filed: 28 September 2000
Title: **Electronically Controlled Engine Generator Set**   Page **20** of **75**

the engine torque curve is at 200 radians per second and 200 meter newtons. At a rotational velocity of 200 radians per second, the engine is providing a torque of 200 meter newtons, or a power of 40 kW. The generator is locked to the engine at 200 radians per second, and with this particular resistive load

5   is providing a torque load of 200 meter newtons. Thus, the engine and generator are in torque equilibrium, and system power output is 40 kW.

When there is a change of operation to a 20 ohm load, the 20 ohm load line also passes through zero torque at zero speed. At 400 radians per second, the generator voltage is 2000 V, and the current through the load is

10   100 amperes, with a power output of 200 kW, and a generator torque of 500 meter newtons. At 200 radians per second, the equilibrium point for a 25 ohm load, the generator voltage is 1000 V, the current through the load is 50 amperes, and the generator torque is 250 meter newtons, considerably more than the torque output of the engine at 200 radians per second. The

15   intersection of the 20 ohm load line and the engine torque curve may be determined graphically to be at about 158 radians per second, with a torque of 198 meter newtons. The generator output voltage is 790 volts, and the current through the load is 39.5 amperes, for a power output of 31.2 kW. By decreasing the load resistance equilibrium operating point is changed and the

20   power output of the engine/generator system is reduced, without the use of a throttle.

At the point that the load resistance is changed to 20 ohm resistance, with the system is at equilibrium with a 25 ohm load, with a power output of 40 kW and a rotational velocity of 200 radians per, at that instant, the

25   generator is still rotating at 200 radians per second, and sourcing 1000 volts. 50 amperes will flow to the load, and at the instant of the change over, 50 kW is being supplied to the load, an *increase* in power output. However the engine/generator system is not in equilibrium, and will slow down, eventually reaching the desired lower power output level.

30   The load resistance may also be changed in a continual fashion, to reduce the surge of output power that occurs with a sudden load resistance change. Going to the opposite extreme, the load resistance may be changed beyond that required by the new equilibrium, to be restored to the equilibrium resistance when the appropriate value when the calculated system

35   speed is reached. This will increase both power surges or deficits, and further increase the rate at which system speed changes.

Title: **Electronically Controlled Engine Generator Set**   Page **21** of **75**

Graphical or mathematical techniques, may be used to determine equilibrium power output of an engine/generator system given a particular resistive load.

5   **Example 2 – Changing the Excitation Frequency**

Another way to change the torque load of a generator involves changing the excitation frequency of the generator, as described above. This changes the synchronous speed, and the difference in initial speed relative to the synchronous speed causes a generator torque change. This causes a changed

10   electrical power output, a changed torque load, and acts to change the engine/generator speed. While these changes are taking place, the load on the generator will see a constantly changing power supply. If this is inappropriate, then excess power supplied will have to be diverted to a secondary load, and a reduced power supply will have to be supplemented from

15   a separate power source. Change in synchronous speed is a technique applicable to AC generators, such as induction or synchronous machines.

In general, to slow down the heat engine, the excitation frequency will be decreased, and to speed up the heat engine, the excitation frequency will be increased. In the case of an AC induction generator operating in its

20   normal operating range, torque changes in an essentially linear fashion about synchronous speed, with zero torque right at synchronous speed, a positive torque load for rotor speeds above synchronous speed, and negative torque loads (motoring operation) below synchronous speed. Real power output will change along with such changes in generator torque, and the electrical load

25   on the generator is compatible with such power output changes, e.g., a resistive load as described above works during generator operation, whereas some sort of battery would be necessary for motoring operations.

It is possible to change the synchronous speed to achieve the desired change in one step. However, large changes in synchronous speed could result

30   in non-desired results. The torque/speed curves have maxima, and the trending in both directions towards equilibria only happens if the torque load is below the generator side maximum. Beyond that point, if the generator torque load is greater than the engine torque, the system may slow down towards equilibrium, but should the generator torque load be lower than

35   the engine torque, then the system will accelerate and continue to do so. Therefore, when the system is to be sped up by a large amount, it may be

necessary to change the generator torque load in stages, to produce a slower and more gradual change.

For example, a slow change may be appropriate if there were no energy storage, a slight lowering in power was desired, and the amount of time
5   needed to reach the new power level was not a factor.

A fast change may be appropriate if there was an energy storage or supply, and the amount of time need to reach to the new power level was a factor.

With reference to Fig. 5, a graph of torque versus speed for both an
10 internal combustion engine and for an AC induction generator connected to an excitation source operating at various frequencies is disclosed. The abscissa of the graph represents speed in radians per second, while the ordinate of the graph represents torque in meter newtons. Curve M represents the torque of the engine, with positive ordinate values representing power
15 output of the engine, that is torque in the direction of rotation. Curves G, G',G'',G''' , etc. represent the torque of the generator with various excitation frequencies, with positive ordinate values representing power consumption of the generator, that is torque in the direction opposite that of rotation. Curves G, G',G'' ,G''' , etc. are labeled with the excitation
20 placed on the generator for each curve. In this particular instance, the excitation voltage is proportional to the excitation frequency, meaning that excitation remains constant. The power electronic drive/load must source or sink current as appropriate to maintain proper operating voltage. Note should also be made of the fact that on each curve, below the excitation
25 frequency, the generator is operating as a motor. It is also useful to note that the generator will act as a motor, and produce torque, at zero speed.

For example, consider an initial condition of the engine and generator not operating. Glow plugs or other startup heat sources may be used in the engine. The power electronic control begins to synthesize alternating
30 current at 100 radians per second (approximately 16 Hz), at suitable voltage for the generator in question. The power electronic control will source considerable current in order to maintain proper operating voltage. The generator will act as a motor, and cause the engine/generator system to start rotation. The engine will consume fuel and air, and start producing power.
35 The combination of the torque provided by the engine and that provided by the generator will cause the engine/generator system to swiftly accelerate past

synchronous speed.   At this point, the generator will begin to convert mechanical power into electrical power, and placing a torque load on the system.   At a system speed of about 108 radians per second, the generator torque will balance the engine torque, and the system will cease to

5   accelerate.   Power output will be about 21 kW.

The power electronic control synthesizes alternating current at 200 radians per second, again as suitable voltage.   The generator is now operating on a new torque/speed curve, and at the current system speed of 100 radians per second will operate as a motor.   The combination of engine and

10   generator torques act to accelerate the system to approximately 208 radians per second.   At this point, equilibrium will obtain with a power output of about 42 kW.   During the initial acceleration phase, the system is actually absorbing power, which must be supplied by energy storage connected to the power electronic converter.

15   For power output reduction, the drive frequency and synthesis speed is to be reduced.   The reduction of drive frequency is limited by the maximum torque range of the generator.   If the synchronous speed is reduced so much that generator torque is less than the torque output of the engine, then the system will start to accelerate and enter a runaway condition.   A runaway

20   condition occurs when the torque output is greater than the maximum torque load of the generator system, such that the speed will continue to increase until the internal friction of the heat engine prevents further speed increase, or until the system fails.

As mentioned above, small changes in synchronous speed may be used to

25   cause slow changes in power output with only small surplus or deficit power output levels.   In situations where such surplus or deficit power is not a problem, extremely rapid changes in power output may be effected.   As described above, the example system is simply capable of starting the heat engine.

30   Specific values of torque, rotational velocity, torque versus slip, and slip are specific to the example engine and generator described above. Different implementations of heat engine connected to induction machine will operate at different torques, slips, and rotational velocities.

Another way to change the generator synchronous speed is to vary the

35   number of magnetic poles developed in the generator. On way to do this is by

Proprietary and Confidential • Property of Borealis Technical Limited
Application for Patent of Jonathan Sidney Edelson, Filed: 28 September 2000
Title: **Electronically Controlled Engine Generator Set**   Page 24 of 75

taking advantage of the pole changing capabilities of motors and generators
having high phase counts, such as a 30 phase generator.

Example 3 - Power Electronic Pseudo-Resistive Load

5   A variable resistive load may be used to control the torque/speed
characteristics of a generator, thereby obtaining control of engine/generator
speed, engine mechanical power output, and thus, engine/generator electrical
power output. Such a load need not be an actual resistor, but may be any
load with a generally resistive character. Of specific interest are loads
10   which have positive incremental resistance; loads for which current will
increase when voltage increases, even if the ratio of current to voltage is
not constant as it would be in a true resistor.

As noted above, there is generally an increase in output voltage as the
generator speeds up. The value of positive incremental resistance is that as
15   the voltage increases, the current drawn by the load will increase,
increasing the torque load of the generator. A generator providing power to
a load with positive incremental resistance will be stable to perturbations
in prime mover speed, because an increase in prime mover speed will cause an
increase in generator torque, acting to slow the system down, while a
20   decrease in prime mover speed will cause a decrease in generator torque,
acting to return system speed to the equilibrium value.

As mentioned above, switching power supplies may operate as constant
power loads, which have negative incremental resistance, and can cause
inherently unstable operation of an engine/generator system. However,
25   switching power supplies may also act as resistive loads, and may be designed
so as to act as pure resistors, or to simply have positive incremental
resistance over part or all of their operational range. Of particular
interest are switching power supplies that draw little or no current until a
particular threshold voltage is reached, at which point they steeply increase
30   their current draw as voltage is increased.

Referring to Fig. 4, the intersections of the high resistance load
lines with the engine load line get increasingly shallower as power output
increases. This means that the natural stability mentioned above will be
reduced. Further, the rate at which engine speed changes in response to

Proprietary and Confidential • Property of Borealis Technical Limited
Application for Patent of Jonathan Sidney Edelson, Filed: 28 September 2000
Title: **Electronically Controlled Engine Generator Set**   Page **25** of 75

commanded change becomes less as power output increases.   This situation may be enhanced through the use of pseudo-resistive loads.

With reference to Fig. 6, a power electronic load is designed so as to operate with positive incremental resistance.   This load draws little or no

5   current until a programmable threshold voltage, at which point current increases at a rate of 0.4 amp per 1 volt change, or an incremental resistance of 2.5 ohms.   The power electronic load is further designed to not draw more than 50 amps, thus, preventing generator overload.   Generator voltage is directly related to rotational speed, while generator torque is

10   directly related to current draw, in this example using the same sample generator as example 1.   Thus, each electrical load line, selected by selecting controller threshold voltage, may be assigned to a generator torque/speed curve.

With most resistive loads, system rotational speed, and thus, power

15   output, is controlled by the equilibrium between generator torque/speed characteristic and engine torque/speed characteristic.   Also, as most loads, the generator torque/speed characteristic is set by the electrical voltage/current characteristic of the load.   The improvement is that power electronic load provides for a rapid change of torque versus speed about the

20   desired equilibrium rotational velocity, thus, improving operational stability at the desired power output.   Further, the current draw of a power electronic load may be limited to a maximum design to not overload the generator.   The incremental resistance of a power electronic load is an aspect of its design, and may be tuned to a particular engine, generator, or

25   load.

A power electronic pseudo resistive load may be used with a DC generator, with a synchronous generator, or with an induction generator, if excitation frequency is not fixed, for example with capacitor excitation.

A power electronic load is quite similar to a power electronic power

30   supply; the essential difference is in the feedback loop.   In a power supply, the output is sampled, and errors in the output are corrected through suitable adjustment of the active control elements.   In a power electronic load, the input is sampled, and errors in the input are corrected through suitable adjustment of the control elements.   Both input side voltage and

35   input current are sampled.   The control element is adjusted so as to maintain a desired relationship between input voltage and input current.   This may be

done by maintaining a constant ratio between input voltage and input current, thereby synthesizing a resistive load. More complex voltage/current ratios may be designed for, and voltage/current ratio may be adjustable. Power electronic loads may also be programmed to sample the frequency of AC current input and maintain desired frequency characteristics.

With reference to Figs. 8, a block schematic diagram of an adjustable threshold constant incremental resistance power electronic load is depicted. The power electronic circuit itself is called in the art a boost converter. Electrical current flow is from the source, through an inductor, through a switching control element, and back to the source. A high voltage load is also connected to the switching element, through a diode. In operation, the switching element is alternately closed and opened at a rapid rate. When the control element is closed, the source is short circuited through the inductor, storing energy. When the control element is opened, the inductor attempts to maintain current flow, and forces current through the high voltage load, dissipating the energy stored in the inductor.

The current flow from the source is controlled by the duty cycle of the control element. Normally, the output voltage would be sampled, and the input current would be adjusted to control output voltage. In the present usage, the input voltage and current are sampled. The input voltage and current are sampled prior to the control element. A threshold voltage is subtracted from the input voltage using a rectifier. The voltage above threshold is now compared with a scaled voltage that is proportional to the current. Any difference between sensed current and desired current is used to drive an integrator, which adjusts the control element. In the case that current flow is exactly that desired, the input to the integrator will be constant, the integrator output will be constant, and the control element will maintain its desired state.

With a power electronic load, the *input* is controlled, and the *output* is varied to maintain the appropriate input. For example, a power electronic load synthesizing a *resistor* will reduce its current consumption in the event that supply voltage is reduced. Output voltage and current will change as appropriate to the new power level. The output may be, for example, a high voltage traction battery used in a hybrid electric vehicle. The power supplied to this battery would change in a fashion controlled by the input voltage to the power electronic load.

Example 4 - Power Electronic Pseudo-Resistive Load with Energy Storage

With the addition of energy storage needed for smooth supply of electrical power to the final load, additional options are available for a power electronic load. A suitably designed power electronic load may be capable of sourcing as well as absorbing power. In some cases, such capability is an inherent part of the load design, in other cases a load must be designed specifically for power sourcing applications. The present example will function with a brush comutated DC generator, or with a brushless DC motor modified with suitable back diodes so as to be capable of generator operation.

The inverter drive for an induction generator must be capable of supplying power to the generator, operating the generator as a motor. This is necessitated by the fact that induction machines consume reactive power. Reactive power means that current and voltage are not in phase, and that energy is circulating between the generator and the inverter. An inverter must therefore include a small amount of energy storage, and must be capable of sourcing a small amount of energy. With the addition of more extensive energy storage on the DC link, the generator may be caused to act as a motor for an extended period.

In the case of a DC generator with independent excitation, the generator may be caused to act as a motor by reversing the flow of armature current through the machine. With reference to Fig. 7, a power electronic load is designed so as to operate with positive incremental resistance and with current sourcing. This "load" actually supplies 10 amperes of current until a programmable threshold voltage, at which point current consumption increases at a rate of 0.4 amp per 1 volt change, or an incremental resistance of 2.5 ohms. At 25 volts above the threshold voltage current is zero, and as voltage rises current consumption increases. The power electronic load is further designed to never draw more than 50 amps, thus, preventing generator overload. However, in conditions of excessive rotational velocity, the generator is allowed to go into overload in order to prevent an engine over-speed condition. The power electronic load supplies electrical power to a high voltage traction battery. Generator voltage is directly related to rotational speed, while generator torque is directly related to current draw, in this example using the same sample generator as

Proprietary and Confidential • Property of Borealis Technical Limited
Application for Patent of Jonathan Sidney Edelson, Filed: 28 September 2000
Title: **Electronically Controlled Engine Generator Set**   Page **28** of 75

example 1. Thus, each electrical load line, selected by selecting controller threshold voltage, may be assigned to a generator torque/speed curve.

Below the threshold voltage, current flows through the generator in the opposite direction of the generator produced voltage; electrical power is being supplied to the generator and the generator is acting as a motor. The power electronic load in this case is acting as a power electronic power supply, producing a terminal voltage which is greater than the generator voltage, thus, causing current flow through the generator. For the example generator, a current of 10 amperes corresponds to a force of 50 meter newtons. As the threshold voltage is reached, current supplied to the generator is reduced, and the generator ceases to act as a motor, and begins to supply power to the load. Equilibrium between engine torque and generator torque load is as before; power output is adjusted by changing the position of this equilibrium by changing the threshold voltage.

Note that the transition between motor cranking, to start the engine, and generator operation, in order to generate electricity, is entirely automatic. If the engine is slow to start, then the engine will not produce torque, and the generator system will continue to act as a motor. Further, there is no need to know the exact speed of the engine. Rather, the threshold voltage is controlled based upon the desired power output. If the system power output is less than desired, then the threshold voltage is increased. Similarly, if too much power is being produced, then the threshold voltage is decreased. Power output may thus be controlled over a large power range.

A circuit may be implemented with the above DC active load with energy storage. With reference to Fig. 8A, a DC generator is connected by means of an inductor, a transistor, and a diode to a battery. The control circuitry, transistor drive circuitry, voltage and current detection means, as well as the specifics of the transistor and diode components, are also included. The battery voltage is higher than the generator voltage, and the configuration of inductor, transistor, and diode is known as a boost converter. During operation, the transistor is switched on and off at a rapid rate. When the transistor is on, the generator voltage is applied to the inductor, causing current to flow and energy to be stored in the inductor magnetic field. When the transistor is switched off, the energy stored in the inductor is used to maintain current flow. The voltage across the inductor changes, increasing

Proprietary and Confidential • Property of Borealis Technical Limited
Application for Patent of Jonathan Sidney Edelson, Filed: 28 September 2000
Title: **Electronically Controlled Engine Generator Set**   Page **29** of 75

to the point that the diode conducts, and energy stored in the inductor is supplied as a charging current to the battery.

With reference to Fig. 8B, the addition of an additional transistor and diode allow for similar operation with the additional capability of supplying power from the battery to the generator. When operating as a load, transistor A is switched as above. With transistor A off, power supply capability is as follows. Transistor B is switched on. As the battery voltage is greater than the generator voltage, current flows through transistor B, the inductor, and then to the generator. This causes the generator to act as a motor. To regulate the current through the generator, transistor B may be switched at a rapid rate; the duty cycle of transistor B controlling the current supplied to the generator. The catch diode and inductor act to provide continuous current flow even as transistor B is switched on and off. When transistor B is switched off, the inductor will maintain current flow, the current flowing through the diode. Transistors A and B are restricted to not being on at the same time. Transistor B, the catch diode, and the inductor form a "buck" converter for supplying power from the battery to the generator. It may be possible to dispense with the inductor entirely, depending solely upon the natural inductance of the motor itself to provide current smoothing action.

Interface of this embodiment of the present invention to an external load is particularly easy. A load is designed so as to consume power at the battery nominal voltage. This may be, for example, the motor of an electric car, operated through a suitable controller. The generator controller monitors the state of charge of the battery, though the simple expedient of measuring actual battery voltage. In response to increasing depth of discharge, or to increasing rate of discharge, the generator controller would command an increase in power electronic load threshold voltage. This would move the engine/generator equilibrium point to higher speeds and power levels. Additional fuel would be consumed, additional power would be delivered to the battery, and the battery would be recharged. As the battery achieves full charge, or as the rate of discharge decreases, the generator controller would command a decrease in power electronic load threshold voltage. This reduces the speed of engine/generator equilibrium, and less power would be delivered to the battery.

Example 5 - Resistive Load with Excitation Control

Generator voltage is directly related to the rotational velocity of the generator rotor. Generator voltage is also directly related to excitation level. At the same rotational velocity, doubling excitation level will

5   roughly double generator output voltage. Doubling excitation level will also double torque for a given output current level. The effects of armature reaction are ignored in this description, since they do not affect the general trends described. If excitation is doubled, with a constant resistive load, then output voltage will be doubled, current flowing through

10   the load will double, and generator torque load and power output will increase by a factor of four. This increase in torque load will cause the engine/generator system to slow down.

Doubling the excitation level will have roughly the same effect as quartering load resistance. A change in excitation level may be understood

15   having the same effect as a change in resistance equal to one over the square of the excitation change.

The method of the present example embodiment is applicable to DC generators with separate excitation. It is also applicable to AC synchronous generators with variable excitation when operating frequency independent

20   loads.

In an exemplary embodiment, a diesel engine provides mechanical power to an AC synchronous generator with external excitation. Electrical power from the generator is used to operate an electrical resistance heater. The diesel engine has a fixed fuel injection setting.

25   When it is desired to increase the heat being produced by the heaters, the generator excitation is reduced. This causes the engine/generator system to speed up, until equilibrium is achieved at a higher rotational velocity, with higher voltage and current. When it is desired to reduce the heat being produced by the heaters, the generator excitation is reduced.

30

Example 6 - Battery Load with Alternator

Of particular value for automotive applications is the use of an alternator as the generator. An alternator is essentially a brushless DC generator, comprising a stator with a three phase winding, and a wound rotor

35   producing a suitable magnetic field, and suitable rectifiers on the stator

circuit to provide a DC output. In most alternators, the excitation is provided by means of current supplied to the wound rotor by means of slip rings. Excitation is generally controlled in an automatic fashion in order to maintain a fixed output voltage over a wide load range. The alternator is

5   of particular value because it is already in common use for automotive applications.

With reference to Fig. 9A, an engine and alternator connected for use in the method of the present invention is shown. In this case, the alternator presents the primary load on the engine, rather than a minor

10   secondary load. The three phase stator winding connects by means of the full wave rectifier to the battery. Control is provided by means of excitation change, similar to example embodiment 5 described above. The battery, however, presents an extremely non-linear load. At low rotational velocity, alternator output voltage is lower than battery voltage, and the rectifier is

15   back biased. Output current is thus, essentially zero, and alternator torque load is minimal. As the alternator output voltage becomes comparable to battery voltage, current and torque increase rapidly, limited only by the extremely low resistances of the battery circuit and by armature reaction.

With reference to Fig. 9B, a graph of torque versus speed for both an

20   internal combustion engine and for an alternator supplying a battery type load, operating at various levels of excitation is shown. The abscissa of the graph represents speed in radians per second, while the ordinate of the graph represents torque in meter newtons. Curve M represents the torque of the engine, with positive ordinate values representing power output of the

25   engine, that is torque in the direction of rotation. Curves G, G',G'',G''', etc. represent the torque of the alternator with various excitation levels, with positive ordinate values representing power consumption of the generator, that is torque in the direction opposite that of rotation. The exact location of the threshold points on the torque/speed curves will depend

30   upon the state of charge of the battery, but the general nature of these curves will remain unchanged.

As may be noted from the diagram, engine/alternator power output is increased by a reduction in excitation, and reduced by an increase in excitation. This may be understood in the context of the present invention

35   as follows: at a given equilibrium rotational velocity, an increase in excitation will cause an instantaneous increase in power output. This

Title: **Electronically Controlled Engine Generator Set**   Page **32** of 75

increased power output is not matched by engine power output, thus the engine/alternator system must slow down. This slowing stops when a new engine/alternator equilibrium is attained. Similarly, a reduction in excitation causes an instantaneous reduction in electrical power output,

5 leaving the engine with excess power to accelerate the system. As the engine is operating in wide open throttle configuration, engine rotational velocity will determine fuel consumption and power output.

An automotive alternator does not normally act as a motor, as the rectifiers are passive commutation devices. However, with the addition of

10 switching elements and a rotor position sensor, an alternator may be modified to act as a brushless DC motor. a modification allows the alternator to act as the starter for the heat engine.

Example 7 -- Generator in Engine Synchronized Periodic Motor Action

15 The introduction of energy storage and motoring of the generator permits further benefit to be had from the present invention. In heat engines, inertia (the energy of motion of an object) is an important factor. During the engine power cycle, inertia carries the pistons through the power absorbing strokes. To enhance this mechanical energy reserve, a flywheel is

20 placed on the crankshaft to which the pistons are connected. The engine must be operating rapidly enough for sufficient energy to be stored in the motion of the flywheel to allow for the completion of power absorbing strokes. If the engine is operating too slowly, it will stall.

Traditionally, a small electric motor is used to start the engine.

25 This motor, also known as the starter, is coupled to the engine and is started by closing a circuit to an independent energy source, usually a battery. When started, the starter rotates the engine until sufficient inertia is reached and one piston can carry the rest of the pistons through their power absorbing strokes on its own. Once the desired speed is reached,

30 the starter is mechanically disconnected from the engine.

As mentioned above, numerous generator designs my be operated as motors, given suitable electronic control and a source of electrical power, such as a battery. The generator, temporarily acting as a motor, may replace the starter to initiate engine operation. Once the engine gains sufficient

35 momentum, the generator is reset to its original function and the power is

provided by the engine. This eliminates the need, and with it the cost and the complication, of a separate starter unit.

As described above, several generator/load combinations act as motors at low speed, transitioning to generator operation engine speed passes a
5 particular threshold. In the method of the present invention, this threshold is controlled by various means suitable to the generator and load. Further, several generator/load combinations display rapid changes in torque with rotational velocity, meaning that a small change in rotational velocity will cause a large change in generator torque load. Such a "stiff" generator, if
10 capable of motor operation, will act as the flywheel of the engine. During power absorbing strokes, the engine/generator system will slow down slightly, and the generator will begin to act as a motor, supplying the necessary energy to the pistons. During power strokes, the engine/generator system will speed up slightly, and the generator will output electrical power to the
15 battery.

Similar results may be obtained through the use of a position sensing mechanism mechanically coupled to the engine, which would command the generator/load controller to appropriate torque levels at appropriate times during the engine power cycle. Such added complexity may beneficially
20 improve efficiency.

There are two particular advantages to the present example embodiment. First, energy stored in a flywheel increases as the square of the rotational velocity. As the engine slows down, a point may be reached where insufficient energy is stored in the flywheel to carry the engine through
25 energy absorbing strokes, and the engine will stall. The electrical energy storage does not show such a low speed limit; thus, an engine operated in the method of the present invention will be capable of operation at arbitrarily low speed, and thus, arbitrarily low power output. Second, the use of the generator and battery in place of the flywheel will allow for the use of
30 single cylinder engines, which are simpler, have smaller surface area to volume ratios, and are more efficient.

Example 8 – Another Embodiment of a Generator in Engine Synchronized Periodic Motor Action

Application for Patent of Jonathan Sidney Edelson, Filed: 28 September 2000
Title: **Electronically Controlled Engine Generator Set**   Page 34 of 75

A single cylinder diesel engine is coupled to an induction generator. The system is operated by electric control that is supplied with DC power by a battery. The electronic control is able to electronically manipulate the current and frequency of the power input to the induction generator. The

5   control is further able to draw power from the battery and provide suitable AC excitation and power to the generator, or to supply suitable AC excitation to the generator while rectifying real power from the generator and supplying power to the battery.

Initiation of system operation is as follows. The control system

10 operates as an inverter to synthesize alternating current of suitable voltage, frequency, and phase so as to cause the generator to operate as a motor, and accelerate the diesel engine to operational speed. The generator, driven by power provided by the control, from the battery, rotates the engine through the intake and compression strokes. Depending upon system inertia,

15 generator torque, and generator synchronous speed, the system may reach the normal operating range at this point, or may take several power cycles for the system to reach the operating range. The normal operating range is that speed range from a few percent below to a few percent above the generator synchronous speed. At the operating range, during the power stroke, the

20 system will speed up above the generator synchronous speed, causing the generator to produce electricity. Then during the power absorbing strokes, the system will slow down below generator synchronous speed, causing the generator to act as a motor, and provide mechanical power to push the heat engine through the power absorbing strokes. Through control of generator

25 synchronous speed, the average system speed may be controlled, thereby controlling the power output of the system. It may be noted that there is no requirement to detect the actual speed of the engine, nor is there need for a sensor to determine the position of the engine in its power cycle. The engine will naturally vary its speed about the synchronous speed of the

30 generator, and power production may be controlled through control of engine synchronous speed.

The above is a description of a single cylinder diesel engine coupled to an electric generator, and a battery, and operated by an electric control. While this description includes many specifics, these, and other descriptions

35 disclosed above, should not be construed as limiting the scope of the invention in any way. For example, the diesel engine, mentioned in the model above, may be replaced with another heat engine equipped with any number of

cylinders, or an Otto cycle engine, or a four cylinder gasoline engine. The engine may or may not be equipped with a turbocharger or an electric supercharger, depending on the manufacture preference. More than one engine may be used to drive the generator, for example, when two very different load

5   modes may require an additional temporary power input, to supply the high load mode. In fact the invention is directed to a prime mover, which may or may not be an engine at all. For example, a water turbine in a dam could utilize the present invention as its control technique, as could other prime movers. It is only for clarity in reading that the prime mover has been

10   referred to almost throughout this specification as an engine, and more specifically, as a heat engine.

The method of the present invention controls the prime mover "fuel" consumption by the motion of the prime mover. Thus, the present invention is suitable for internal combustion engines, pressure operated reciprocating

15   engines, turbine systems over restricted speed ranges, etc. As an example of a system for which the method of the present invention is unsuitable, one may consider a wind turbine, in which the wind blows weather power is being consumed or not. Similarly, a standard twin shaft gas turbine engine, in which the power output shaft is not directly connected to the compressor or

20   fuel supply.

More than one generator may be coupled to the engine as a result of space requirements, separate operational need or other consideration. The engine may be coupled, in addition to the generator, directly to the load; for example, in a vehicle, the engine may be, in addition, coupled to the

25   wheels. As in the model, any type of generator may be used for the conversion of the mechanical power to electrical power. Any type of generator that is capable of acting as a motor may be used in an embodiment that takes advantage of this capability. The present invention teaches how control could be effected without the need for throttle control. There are

30   however embodiments in which a throttle would be part of the engine generator system, e.g., for shutdown, or as a safety device. Power electronic devices for the control and conversion of the electrical power are not limited to those listed, but may include any power electronic switches, including gas discharge devices, mechanical switches, silicon devices, and vacuum

35   microelectronics devices. The extent of the control might range from the manipulation of the generator's output, through control over the generator's excitation levels, to the additional control over the engine's fuel and air

Title: **Electronically Controlled Engine Generator Set**   Page 36 of 75

intake. Operation is not limited to the ideal combination of engine speed, winding power and generator electric load, although the invention facilitates operation at such ideal parameters. Direct feedback of heat engine speed may be used to allow the power electronic control to anticipate power output

5 corrections. In addition, other feedback parameters such as engine and winding heat, oxygen concentration in the exhaust path etc. may be collected, depending on the machine function, to reflect the difference between the given condition and the desired one. The power electronic control system may control system rate of speed change, as well as system speed. The power

10 electronic control system may include predictive capability to anticipate future power requirements, and to select power output levels accordingly. The generator controller used to alter the synchronous speed of the generator according to the methods described may include standard field oriented control techniques, which allow the control of electrical machine torque

15 versus speed relations.

While inherently stable embodiments have been described, in which small changes in system speed cause immediate changes in power consumption which restore the system to the desired equilibrium speed, such is not a necessary requirement. The requirement of equilibrium may be met through the use of

20 unstable equilibrium, for example a DC generator supplying a constant power switching load. In such a case, active changes in load power consumption will be needed to maintain system speed, however the unstable nature of the engine/generator equilibrium may enhance the speed with which power output levels may be changed. There are also embodiments in which a further

25 controlling step will prove necessary, to cause the engine and generator to be in an equilibrium state, so that the engine stops changing speed.

There have been described embodiments in which the focus is on the change of power output of the engine, via generator control. Another application of the present invention is with the use of an induction

30 generator having a very high torque to speed relation around synchronous speed. Through this, the generator fluctuates between generating and motoring modes throughout the engine power production cycle itself. As a result, the engine never slows down dramatically during power absorbing strokes, to speed up again dramatically in power production strokes. In such

35 an embodiment, used perhaps in a electricity generation unit, the generator may, or may not also provide control over the output of engine; indeed a throttle may be used to control engine power output.

Some embodiments may use a more limited and some a more expanded control depending on their specific needs. An energy storage unit, such as a battery, may or may not be used. The benefits from the use of the present invention are especially apparent when the invention is utilized in hybrid electric vehicles, heavy machinery and off grid electricity production.

The need for cleaner, more efficient drive means is well established in these fields. However, the benefits of the present invention are not limited only to these examples. In times when environment issues are in the interest of both the public and the legislator, cleaner and more efficient means to produce electrical power are clearly useful and have a great commercial potential.

While this invention has been described with reference to illustrative embodiments, it is to be understood that this description is not intended to be construed in a limiting sense. Modifications to and combinations of the illustrative embodiments will be apparent to persons skilled in the art upon reference to this description. It is to be further understood, therefore, that changes in the details of the embodiments of the present invention and additional embodiments of the present invention will be apparent to persons of ordinary skill in the art having reference to this description. It is contemplated that such changes and additional embodiments are within the spirit and true scope of the invention as claimed below.
